**ABSTRACT**

The bacteria *Helicobacter pylori* (*H. pylori*) have been identified in the extragastric tissues in the head and neck. The origin and pathogenicity of these bacteria in the head and neck are not known. Gastric reflux and nasal or oral routes are the possible modes of spread. In many sinonasal, pharyngeal, laryngeal, and middle ear disorders, laryngopharyngeal reflux has been identified as a contributing or causative factor. One possible mode by which laryngopharyngeal reflux may contribute is by seeding of the extragastric mucosa with *H. pylori*. The clinical significance of the discovery of *H. pylori* in extragastric tissues in the head and neck is unclear. There is no evidence of a pathologic or active role of *H. pylori* in otorhinolaryngological disorders. The suggestion that the sinonasal cavities and pharynx may serve as a reservoir for *H. pylori* and that reinfec-
tion of the stomach occurs after eradication therapy awaits further studies for confirmation. No connection was observed between *H. pylori* found in the stomach and *H. pylori* found in the head and neck. Also, these bacteria, found in the head and neck tissues, may be accidental or innocent bystanders that do not affect the pathways of otorhinolaryngological and gastroesophageal diseases. This review examines the evidence for a possible relationship of *H. pylori* with otorhinolaryngological diseases.

**Keywords:** *Helicobacter pylori*, otorhinolaryngology, laryngopharyngeal reflux, nasopharyngeal reflux

**Introduction**

Although the role of the bacteria *Helicobacter pylori* (*H. pylori*) in gastroesophageal disease is well established, the clinical significance of the discovery of *H. pylori* in extragastric tissues in the head and neck is unclear. This review examines the evidence for a possible relationship of *H. pylori* with otorhinolaryngological diseases.

**Bacteria *H. pylori* in the Nose and Paranasal Sinuses**

Chronic rhinosinusitis (CRS) is a clinical syndrome with many extrinsic and intrinsic etiological factors. It is considered that, among other potential factors, bacterial infection, colonization, allergy, and superantigen may play a causative or contributory role. Gastroesophageal reflux, or more precisely nasopharyngeal reflux, is thought to be a contributing factor in refractory CRS [1]. The exact mechanism by which nasopharyngeal reflux may contribute is unknown. One possibility is the sowing of the nasal mucosa with *H. pylori*, bacterium prevalent in gastric contents. *Helicobacter pylori* was found in the nasal cavity and paranasal sinuses (Figure 1).

Ozdek et al. [2] were the first to report the presence of *H. pylori* in the sinus mucosa. Using nested polymerase chain reaction (PCR), *H. pylori* was detected in the ethmoidal mucosa in 4 of 12 patients with CRS, but it was not detected in 13 CRS-free patients with the concha bullosa. Interestingly, using real-time PCR, Oztyr et al. [3] detected *H. pylori* *ureA* gene more often in the normal nasal mucosa than in the nasal polyps samples (70% vs. 59%, respectively). *Helicobacter pylori cagA* was identified in both *H. pylori*-positive normal nasal mucosa and nasal polyp samples (90% and 79%, respectively). Conversely, in the study of Burduk et al. [4], all 30 nasal polyps and concha bullosa specimens were *H. pylori* cagA negative, but *H. pylori* *ureA* was found by PCR in all 30 nasal specimens. In contrast to aforementioned studies, Ozcan et al. [5] reported that all nasal polyps from 25 patients were *H. pylori* negative by immunohistochemistry (IHC). Using PCR and Giemsa stain, Cedeno et al. evaluated *H. pylori* in 28 children with CRS without polyps. Highly sensitive and specific primers (i.e., *ureC*, vacA, cagA, and babA) were used, but *H. pylori* was not

detected in samples from the antral lavages or adenoids [6].

The following studies have raised a question about an active role of \textit{H. pylori} in CRS. Compared with rhinologic patients without CRS, a statistically significant higher prevalence of sinonasal \textit{H. pylori} in patients with CRS was found [7, 8]. Koc et al. [7] reported that nasal polyps were positive in 6 of 30 patients with CRS, whereas none of the control group samples were positive for \textit{H. pylori} using IHC. In the study of Kim et al. [8], nasal specimens in 12 (out of 48) patients with CRS and in 1 (out of 29) patient without CRS were \textit{H. pylori} positive by both rapid urease test (RUT) and IHC analysis. There were no significant differences between \textit{H. pylori} positive and \textit{H. pylori} negative patients with CRS when comparing their preoperative rhinosinusitis symptom scores and the preoperative disease extent assessed by sinus computed tomography scoring system. A great proportion of degenerative coccoid shapes were found by IHC [8]. Kariya et al. [9] demonstrated that the whole-cell proteins of \textit{H. pylori} in a viable but not culturable state, not exclusively live bacteria, can induce immunological inflammation in the extragastric epithelium. It has been suggested that these coccoid forms constitute a dormant resistant form of the bacterium that may revert into an infectious spiral form in appropriate conditions and result in recrudescence of infection [10]. These findings imply that the sinonasal cavities may be a reservoir for \textit{H. pylori} and possible gastric colonization rather than that \textit{H. pylori} having an active role in CRS. It is not clear why \textit{H. pylori} has been presented in the coccoid form. The use of antibiotics may be one possible explanation [10]. Long-term antibiotic therapy (e.g., clarithromycin for \~{}12 weeks) is included in the CRS treatment scheme and is performed by a number of rhinologists. If there is a failure of maximal medical therapy after 3 months, sinus surgery is considered in medically refractory CRS, as it was performed in aforementioned studies. Furthermore, the nasal cavities with good ventilation can provide an unfavorable oxygen excess. On the other hand, diseased ethmoids and massive polyposis can result in many poorly ventilated and drained narrow spaces. Such spaces can be a favorable environment for microaerophilic \textit{H. pylori}.

The results of Dinis et al. [11] regarding \textit{H. pylori} and pepsin/pepsinogen I status in the ethmoidal and sphenoidal mucosa did not support the notion that \textit{H. pylori} and laryngopharyngeal reflux (LPR) had an important role in the etiopathogenesis of CRS. No significant differences were found between patients with CRS and without CRS controls neither in the blood and mucosa pepsin/pepsinogen I values nor in the \textit{H. pylori} sinonasal colonization. In both groups, the sinonasal tissue pepsin/pepsinogen never rose above blood levels. This finding implies that \textit{H. pylori} colonizes the sinus mucosa via a nasal or oral route rather than via a gastric reflux. The authors state that when in comorbidity, the pathogenic mechanisms of \textit{H. pylori} infection and reflux disease probably run in a parallel fashion, independent from each other [11]. Also, it is possible that \textit{H. pylori} colonizes the vulnerable damaged sinonasal mucosa, as a favorable harbor; after CRS is already developed. In that case, \textit{H. pylori} colonization is the consequence, but not the cause, of CRS.

A possible predictive value of \textit{H. pylori} sinonasal colonization for efficacy of endoscopic sinus surgery in patients suffering from CRS with nasal polyps has been studied [12]. Nasal polyps in 28 of 40 (70%) patients were positive for \textit{H. pylori} by IHC. There were no significant differences between the \textit{H. pylori} positive and \textit{H. pylori} negative group comparing the nasal polyp eosinophils and the postoperative improvement of the CRS symptom scores. There was a prognostic value for the endonasal findings: compared with CRS patients with \textit{H. pylori} negative nasal polyps, patients with \textit{H. pylori} had statistically significant greater improvement in postoperative endoscopic scores [12]. Physicians who oppose “total war” against \textit{H. pylori} might be delighted with this result. There is no consensus about Blaser’s suggestion that in addition to “bad” and “very bad” \textit{H. pylori}, “neutral” or “good” ones also exist [13]. A possible positive influence of \textit{H. pylori} on asthma has been reported and explained by the ability of some \textit{H. pylori} compounds to drive T helper-1 polarization and to display a powerful inhibition of allergic T helper-2 response [14]. CRS is one of the most frequently encountered comorbid conditions associated with asthma. The current findings regarding a prognostic role of \textit{H. pylori} in CRS must be interpreted with caution. The status of the most important \textit{H. pylori} virulence factors was not determined [12]. Theoretically, there may have been a state of preponderance of VacA negative and CagA negative strains that may have influenced histological and clinical findings. Further studies, including a larger sample size, and stronger validated tools for assessment of CRS severity and determination of \textit{H. pylori} virulence factors are needed. The most relevant studies presenting the current state of knowledge on the relationship between \textit{H. pylori} and CRS are shown in Table 1. A pathological or active role of \textit{H. pylori} in CRS was not established.

\textbf{Bacteria \textit{H. pylori} in the Pharynx}

The study of Minocha et al. [15] has stimulated research on tonsils as a possible natural reservoir—extragastric site at which \textit{H. pylori} evades treatment. They found a decreased prevalence of \textit{H. pylori} gastric colonization in subjects with
a history of tonsillectomy. The suggestion that tonsillectomy may protect the host against *H. pylori* infestation of the stomach has arisen, although contrary reports exist [16]. Fibrotic tonsils with debris trapped in crypts are a good environment, and they may be a permanent reservoir for microorganisms [17]. Tonsils, a component of mucosa-associated lymphoid tissue, are the first line of mucosal defense against invading pathogens. In the study of Skinner et al. [18], *H. pylori*-seropositive patients exhibited a higher expression of inducible nitric oxide synthase in the tonsillar macrophages than *H. pylori*-seronegative patients. It can be hypothesized that *H. pylori* may be an initiating trigger or factor resulting in an exaggerated inflammatory tonsillar response to otherwise commensal organisms [18].

Using PCR, Cirak et al. [19] found *H. pylori* DNA in tonsillar core or adenoid samples in 7 of 23 (30%) patients. The CagA gene was detected in adenotonsillar samples in 5 patients. Zhang et al. [20] detected *H. pylori* in the pharyngeal mucosa in 19 (out of 50) patients with chronic pharyngitis, and in zero of 20 healthy controls. *Helicobacter pylori* may be a cause of inflammation or a marker for reflux and chemical inflammation of the pharyngeal mucosa caused by gastric acid [20]. Using immunofluorescence and immunoelectron microscopy, the study of Kusano et al. [21] on 55 patients with recurrent pharyngotonsillitis or IgA nephropathy (IgAN) demonstrated the cocoid form of *H. pylori* in the palatine tonsils of 43 patients. CagA was expressed in 38 of the 43 strains of tonsilar *H. pylori*. No tonsilar *H. pylori* could be cultured. All 15 patients with gastric *H. pylori* had *H. pylori* in their tonsils. The prevalence of tonsillar *H. pylori* in patients with IgAN (100%) was significantly higher than that in patients with recurrent pharyngotonsillitis (71%). *Helicobacter pylori* may be a candidate for IgAN-pathogenic antigen [21]. It is unclear if the detection of adenotonsillar *H. pylori* represents transient or persistent colonization. Also, the origin of adenotonsillar *H. pylori* is not known. *H. pylori* may have reached the pharynx via a nasal or an oral route or by refluxed gastric content. Lukes et al. [22] detected different strains in the stomach and oropharynx in the same individuals. The oral presence of *H. pylori* without concurrent stomach infection was found. According to these findings, the *H. pylori* oropharyngeal colonization seems to be independent to the gastric infection.

This fastidious bacterium is difficult to culture from oropharyngeal specimens because of more robust flora competing for a growth. In the study on 62 palatine tonsils and 77 pharyngeal tonsils in 77 children [23], 17 palatine tonsils in 14 children were RUT positive and *H. pylori* negative. Eight children were positive for both RUT in tonsils and 13Carbon-urea breath test. No significant difference was observed between children with tonsillar hypertrophy and those with recurrent tonsillitis in *H. pylori* patients with chronic tonsillitis in comparison to patients with tonsillar hypertrophy. They also reported significant correlation of *H. pylori* colonization with laryngeal signs of LPR [24].

Yilmaz et al. [25] were the first to isolate *H. pylori* from the pharyngeal tissue culture. Out of 22 children, there was a growth of *H. pylori* in the cultures of adenoids and tonsils in 11 and 12 patients, respectively. These findings were supported by positive PCR. In contrast, in the study of Bitar et al., all 25 adenoids tested were *H. pylori* negative by nested PCR [26]. Contradictory results exist regarding the presence of *pylori* *H. pylori* in the studies performed on populations from the same country [25, 26]. It is not known if cognition of patchy distribution of *H. pylori* in the stomach may be applied to the pharynx. In that case, the number of samples taken from one site can affect the results.

In the study of Vilarinho et al. [27] on 46 palatine tonsils and 55 adenoids in 62 children, 3 tonsils in 2 *H. pylori*-seronegative children were IHC positive, but all the specimens studied were negative by PCR, directed to the vacA gene, and by fluorescence in situ hybridization with a specific *H. pylori* peptide nucleic acid probe. The authors did not consider the adenotonsillar tissue as a permanent reservoir for *H. pylori* infection [27]. There is no evidence of a pathological or active role of *pylori* *H. pylori*. The suggestion that the pharynx may serve as a reservoir for *H. pylori* and that reinfecation of the stomach occurs after eradication therapy awaits further studies for confirmation. This attitude is consistent with the results of other studies [6, 18, 28]. The most relevant studies presenting the current state of knowledge on the relationship between *H. pylori* and adenotonsillar pathology are shown in Table 2.

hoarseness, globus pharyngeus, throat clearing, and cough. The role of \( H. \) pylori toxins in gastric contents that reflux to the larynx and hypopharynx in laryngopharyngeal manifestations is uncertain. No relationship between gastric \( H. \) pylori infection and LPR was reported [29]. Conversely, Oridate et al. [30] demonstrated a lower laryngopharyngeal symptom-improvement rate influenced by acid-suppression therapy among \( H. \) pylori-seronegative patients than among \( H. \) pylori-seropositive patients with gastroesophageal reflux disease. In the study of Çekin et al. [31] using real-time PCR, laryngeal \( H. \) pylori and LPR were found in 56% and 70% of 43 patients with laryngeal lesions, respectively. Helicobacter pylori was detected in 18 of the 30 LPR-positive patients and in 6 of 13 LPR-negative patients. A statistically significant relationship of LPR positivity with malignant or premalignant laryngeal lesions and no association between laryngeal \( H. \) pylori and laryngeal lesions were found.

The bacterium \( H. \) pylori is the first formally recognized bacterial carcinogen [32]. A possibility that \( H. \) pylori may increase susceptibility to head and neck carcinoma, and not just to gastric carcinoma, is an important subject of research. The laryngeal epithelium has its origin in the respiratory diverticulum of the ventral wall of the foregut, and it embryologically develops from the same endodermal cells that line the gastric mucosa [33]. Compared with cancer-free controls, a significantly higher prevalence of \( H. \) pylori seropositivity was found in patients with laryngohypopharyngeal carcinoma [34]. Contrary reports also exist [35].

In the study of Titiz et al. [36], an association between laryngeal \( H. \) pylori and laryngeal carcinoma was found. All benign laryngeal lesions were \( H. \) pylori negative by PCR, but laryngeal \( H. \) pylori was found in 17 of 21 patients with laryngeal carcinoma. Of those 17 \( H. \) pylori-positive patients, \( H. \) pylori was detected in the normal laryngeal tissue only, tumor tissue only, and in both normal and cancerous areas.

tumor tissues in 8, 1, and 8 patients, respectively. All tissue cultures were H. pylori negative [36]. In the study conducted in Egypt [37], PCR was used to detect H. pylori ureA and cagA genes in 49 patients with laryngeal carcinoma and 15 patients with laryngeal benign polyps. A significantly higher incidence of H. pylori was found in carcinoma specimens (65%) in comparison to benign polyps specimens (20%). These findings supported a positive association between H. pylori laryngeal colonization and susceptibility to develop laryngeal carcinoma [37]. Amizadeh et al. reported contradictory results suggesting the protective effect of laryngeal H. pylori against laryngeal carcinoma [38]. Iranian patients with laryngeal carcinoma had lower incidence of laryngeal H. pylori and statistically significant lower incidence of cagA gene than those with benign laryngeal lesions [38]. Using PCR, Yilmaz et al. detected laryngeal H. pylori in only 1 case out of 74 Turkish patients with laryngeal carcinoma [39]. The presence of laryngeal H. pylori DNA in all 30 patients with benign laryngeal lesions [4] and in 59% of 29 patients with benign or malignant laryngeal diseases [3] was reported. Helicobacter pylori cagA was found in 23% and 82% of these H. pylori-positive patients, respectively [4, 3]. Like in neighboring organs, the character and origin of such H. pylori colonization are not determined. A descending or ascending approach from the nose, mouth, and pharynx or stomach is possible. A pathological or active role of H. pylori in laryngeal disorders was not proved. Improved knowledge on the mechanisms responsible for H. pylori-associated gastric carcinogenesis may enhance research on a relationship between H. pylori and laryngeal malignancies. The most relevant studies presenting the current state of knowledge on the relationship between H. pylori and laryngeal disorders are shown in Table 3.

MEE: middle ear effusion; MEM: middle ear mucosa; OME: otitis media with effusion; IHC: immunohistochemistry; PCR: polymerase chain reaction; S: significant difference

### Bacteria H. pylori in the Middle Ear

Otitis media with effusion (OME) is a chronic inflammatory disease characterized by conductive hearing loss and the persistence of a middle ear effusion for at least 3 months without clinical signs and symptoms of active infection. It is not clear why OME develops. In the study of Tasker et al. [40], a possible role of gastroesophageal reflux in the disease pathogenesis has been studied. In 91% (out of 65) samples from children undergoing myringotomy for OME, pepsin/pepsinogen levels in the middle ear effusion samples were up to 1000 times higher than serum levels, indicating that pepsin in the middle ear was almost certainly due to reflux of gastric contents. Immunohistochemical analysis of biopsy samples from the middle ear showed no evidence of pepsin production by the middle ear [40]. Reflux of gastric acid and pepsin into the nasopharynx and eustachian tubes may have led to chemical inflammation and edema of the nasopharyngeal mucosa and dysfunction of the eustachian tube. These findings suggest that anti-reflux therapy may play a part in OME treatment.

Morinaka et al. [41] have reported that immunostained smears revealed H. pylori in 12 (80%) middle ear effusion specimens from 15 patients with OME, mostly adults. Since the adenoid tissue has been incriminated as a source of microorganisms causing the middle ear disease, adenoidectomy is a common procedure as a part of OME treatment. Although the study of Fancy et al. [42] demonstrated that H. pylori gene by PCR in 23 of 73 (32%) middle ear fluid samples from children with OME, the H. pylori prevalence rate in the adenoids of children with OME did not differ from those in the adenoids of OME-free children. Conversely, Bitar et al. [43] failed to detect H. pylori in all 28 middle ear effusion samples from 18 children with otitis media using culture and PCR. The study of Pitkäranta et al. [28] has shown H. pylori negative cultures of 12 middle ear fluid samples in all 8 examined children with recurrent otitis media.

Yilmaz et al. [25] were the first to show the growth of H. pylori in cultures of the middle ear fluid and tympanic mucosa. Compared with the healthy ears of controls, a statistically significant higher prevalence of H. pylori in the middle ear of children with OME was found using culture and PCR. The presence of viable and culturable H. pylori indicates that the middle ear with insufficient ventilation can be a favorable environment for H. pylori. In a study on rabbits [44], after inoculation of H. pylori in the tympanic cavity, H. pylori was cultured in 6 of 8 ears with histamine-induced inflammation, but not in any of the 8 normal middle ears. According to the previously reported findings [25, 40], transmission of H. pylori from the stomach to the middle ear by reflux might occur in humans. Also, an approach via a nasal or an oral route is possible. Association, not causation, of OME with reflux and H. pylori was established. It seems plausible that refluxed acid and pepsin or H. pylori or both together have a role in the pathogenesis of OME. Helicobacter pylori may be a cause of inflammation, a marker for reflux and chemical inflammation caused by gastric acid, or an innocent bystander. The histopathological findings of the rabbit middle ears with histamine-induced inflammation, inoculated by H. pylori, suggest that H. pylori cannot initiate otitis media alone, but can contribute to the inflammation process in the presence of an effusion [44]. The in vivo study on mice [9] indicated that H. pylori might cause immunological inflammation in the middle
ear epithelium. Helicobacter pylori whole-cell proteins directly injected into the tympanic cavity stimulated release of inflammatory mediators and induced inflammatory cell infiltration into the middle ear epithelium in mice.

Saki et al. [45] investigated a possible relationship between H. pylori and tympanosclerosis. Using PCR, they detected tympanic H. pylori in 34 of 56 (61%) Iranian patients with chronic otitis media. Their results suggested an association between H. pylori and tympanosclerosis development. A total of 19 patients with tympanosclerosis had statistically significant higher prevalence of tympanic H. pylori in comparison with 37 patients suffering from other forms of chronic otitis media (84% and 45%, respectively) [45]. Contradictory results suggesting a lack of association between H. pylori and tympanosclerosis were reported by Dinç et al. The tympanosclerotic plaques in all of their 35 patients with tympanosclerosis were PCR negative for H. pylori [46]. The most relevant studies presenting the current state of knowledge on the relationship between H. pylori and OME are shown in Table 4. A pathological role of H. pylori in the middle ear disorders in humans was not established.

Conclusions

The bacteria H. pylori have been identified in the extragastroic tissues in the head and neck. The origin and pathogenicity of these bacteria are not known. Gastric reflux or nasal or oral routes are the possible modes of spread. The clinical significance of such H. pylori colonization is debatable. No connection between H. pylori found in the stomach and H. pylori found in the head and neck was established. The suggestion that the sinonasal cavities and pharynx may serve as a reservoir for H. pylori and that reinfection of the stomach occurs after eradication therapy awaits further studies for confirmation. There is no evidence of an active role of H. pylori in otolaryngological disorders, and a cause-effect correlation was not established. These bacteria, found in the head and neck tissues, may be accidental or innocent bystanders that do not affect the pathways of otolaryngological and gastroduodenal diseases. There is a lack of evidence to perform H. pylori testing for otolaryngological disorders. Previous studies on this topic are conflicting. The role of H. pylori in some otolaryngological disorders is likely to receive greater research attention.

Clinical and Research Consequences

According to the current state of knowledge, H. pylori testing for otolaryngological diseases is not recommended. Also, there is no need for specific anti-H. pylori therapy in otolaryngological diseases.

Recommendations for Future Research

Since the discovery of H. pylori has fundamentally changed the paradigms regarding causation of gastric diseases, investigators should be open-minded about the possibility that H. pylori contributes to some head and neck diseases. More research on the bacterium’s infectious and immunological properties should test the hypothesis that H. pylori may cause head and neck diseases even distal from the primary site of infection in the stomach by interfering with different biological processes. Further studies on this issue will need to include a larger sample size, stronger validated tools for assessment of disease extent and severity, and determine the status of the most important H. pylori virulence factors. While respecting ethical standards, invasive determination of the stomach H. pylori status and typing of H. pylori isolates are needed to show if H. pylori found in the head and neck is the same as that found in the stomach. Continuous advancements in analytical technology and molecular techniques for bacterial identification should be used for accurate identification of H. pylori. Future studies should determine the modes of spread of the bacteria into the head and neck and whether colonization is occasional or persistent. More information about H. pylori activities in patients with oral, pharyngeal, and laryngeal carcinogenesis is warranted.
